#690

Summary

This study primarily investigated univariate and multivariate statistical models in the context of their relative ability to serve as a market earnings expectation model (EEM). As a secondary consideration we evaluated relative ability of these models to generate ex ante forecasts. Included were univariate time series models, bivariate regression models and two bivariate multiple time series (transfer function) models developed by the authors. To accomplish the primary purpose, the models were compared on: (1) how well they are specified based upon diagnostic statistics; (2) their ability to perform in a capital market context; and (3) ex post forecast accuracy.

It was found among models using quarterly data that a simple transfer function (author model 1) provided the best model. Such a model clearly out performed all other quarterly models based on all of the criteria used to evaluate the relative ability of these models to approximate the market expectation of earnings.

A growing body of literature has dealt with statistical models for quarterly earnings. This research has grown along two lines: 1) statistical models have been compared based on their relative ability to approximate the capital markets' expectation when measuring market reaction to accounting data, 2) they have been compared based on their relative ability to forecast future earnings.

The purpose of this paper lies primarily in category one and secondarily in category two. Specifically, the primary purpose of the present research is to bring together many of the various statistical models of earnings used in the literature and assess their relative ability to approximate the market's expectation for earnings in the context of the capital market. A major reason for considering how well a given model approximates the market expectation for earnings is that research in the accounting informational/capital market literature (e.g., Ball and Brown [1968], Beaver [1968], Beaver and Dukes [1972], Brown and Kennelly [1972], Joy et al. [1977] and Kiger [1972] relies upon the choice of an earnings expectation model. For example, Foster [1977, p. 2] wrote: "choice of an inappropriate model (one inconsistent with the time series) may lead to erroneous inferences about the information content of accounting data." Also the use of an earnings expectation model has been important to studies relating to the estimation of the cost of capital, dividend policy and the association of alternative earnings measures (see Foster [1977] for references).

A motivation for the present study is that in most of the previous research, the particular choice of an earnings expectation model (henceforth EEM) was made in an ad hoc fashion without specifically comparing

the applicability of alternative EEM's. This is because there has been a paucity of research dealing with assessing various models and their ability to generate expectations consistent with those of the market. Foster [1977] recognized this problem and compared a proposed model to several previously considered models and his results indicated that the capital markets' EEM includes both quarter-to-quarter and seasonal components. Subsequent research [Collins and Hopwood, 1980] found that the models studied by Griffin [1977] and Watts [1975] and Brown and Rozeff [1979] produce forecasts more accurate than those of the model considered by Foster. These studies, however, focused on forecast accuracy and not on the ability of a model to approximate the markets' EEM. In addition, none of these studies, including Foster's, considered the relative ability of univariate versus multivariate models to approximate the market EEM. This is important because previous information content studies have relied upon both of these types of models. In addition both types of models rely on different information. The univariate models typically generate an expectation based on previous earnings alone (e.g., Beaver and Dukes [1972], Joy et al. [1977], Kiger [1972] and May [1971]), while multivariate models are based on the relationship between earnings and a market index [e.g., Ball and Brown [1968], Beaver [1968] and Brown and Kennelly [1972]]. Therefore, in the present study, both univariate and multivariate models will be examined for their ability to approximate the market EEM. In addition we will examine a new transfer function model which simultaneously utilizes the information of both model types.

The paper is presented in six major parts. In the first and second parts previous models are discussed and our research design presented.

Part three presents diagnostic statistics relating to the specification of the models. This section also introduces the transfer function model. Part four evaluates the models' relative ability to approximate the market expectation as measured in the context of the capital asset pricing model. Part five presents data on forecast accuracy. Part six gives a summary and conclusions.

## 1.0 Background

### 1.10 Models Previously Used in the Literature

Earnings expectation models can be classified as univariate and multivariate. We use the term multivariate to include models which consider the structural relationship between two or more variables. These include the model of Ball and Brown [1968] who regressed an index of annual market earnings changes against the annual earnings changes of individual firms. This model is of the form:

$$(1) \quad (y_t - y_{t-1}) = \alpha + \beta(x_t - x_{t-1})$$

Where  $y$  represents the annual earnings of the firm,  $x$  represents the market earnings index and  $t$  is a time subscript denoting a particular year. Also,  $\alpha$  and  $\beta$  are estimated using historical data.

Similarly, Brown and Kennelly [1972] used the same model but applied it to quarterly instead of annual data. Henceforth, these will be referred to as the BB and BK models. (We use these abbreviations for convenience and do not wish to imply that the authors necessarily advocated the general use of these models.)

A priori, both the BB and BK models have strong points. First, both define the expected earnings in terms relative to the market's

earnings. A possible strong point about this type of expectation is that it eliminates the effect of market fluctuations on the individual firm expectation. As long as a firm maintains a constant earnings relation to the market from period to period, there will not be an unexpected earnings.

On the other hand, both the BB and BK models do not explicitly model earnings performance of a firm relative to previous performance for the same firm. In other words, the times-series properties of earnings are not explicitly modeled. The BK model also ignores the fact that firm earnings are seasonally correlated and therefore is likely to have a problem of auto-correlated residuals.

Unlike the bivariate regression models the univariate models ignore the firm's relation to the economy but explicitly model the time-series properties of the earnings number. Collins and Hopwood [1980] studied the major univariate time-series models found in recent literature. These include: (1) a consecutively and seasonally differenced first order moving average and seasonal moving average model (Griffin [1977] and Watts [1975]), (2) a seasonally differenced first order auto-regressive model with a constant drift term (Foster [1977]), and (3) a seasonally differenced first order auto-regressive and seasonal moving average model (Brown and Rozeff [1978, 1979]). In the Box and Jenkins terminology, these models are designated as  $(0,1,1) \times (0,1,1)$ ,  $(1,0,0) \times (0,1,0)$  and  $(1,0,0) \times (0,1,1)$  respectively. In this study, they are referred to as the GW, F, and BR models. (Again, we use these abbreviations for convenience and do not wish to imply that the authors necessarily advocated the general use of these models.)

Collins and Hopwood [1980] found that the BR and GW models produced annual forecasts more accurate than the F model. In addition, they concluded that they also did at least as well as the more costly individually identified Box-Jenkins (BJ) models. As previously mentioned, these models have not been all related to capital markets. Nor have they been compared to the multivariate models of BB and BK.

## 2.0 Research Design

As mentioned above, the primary purpose of the present study is to evaluate the various statistical forecast models used in the literature on the basis of their relative ability to approximate the market's expectation for earnings. It is important to note that this is not an evaluation which specifically compares models based upon their ability to generate ex ante forecasts. For example the EEM's used by Ball and Brown [1968] and Brown and Kennelly [1972] generate an earnings expectation for time  $t$  based on data for the same time  $t$ . In these cases no ex ante forecasting is done but both models generate "forecasts" of the earnings number. To some this might seem like rather odd use of the term "forecast" since here it is not the future but the present which is actually being forecasted. Nevertheless this usage is common in the literature (including the research of Ball and Brown [1968] and Brown and Kennelly [1972]) and is adopted for the remainder of this paper. To avoid confusion we will use the term ex ante forecast to refer to a forecast of future earnings, and the term ex post forecast to refer to the case where the forecast for time  $t$  is based upon the data known at time  $t$  (e.g., a market index of earnings).

### 2.10 Model Assessment Criteria

Our research design evaluates the various EEM's based upon three criteria:

- 1) How well they are specified based upon diagnostic statistics
- 2) Their relative ability to approximate the capital market as measured by the Capital Asset Pricing Model
- 3) Forecast accuracy.

Each criterion is discussed in detail below, however the present section discusses the basic rationale behind using these criteria. The rationale for criteria 1 and 3 were elaborated upon by Brown and Kennelly [1972, p. 404]:

This experimental design permits a direct comparison between alternative forecasting rules....The...contention is based on the hypothesis (and evidence) that the stock market is "both efficient and unbiased in that, if information is useful in forming capital asset prices, then the market will adjust asset prices to that information quickly and without leaving any opportunity for further abnormal gain" (Ball and Brown, 1968). There is, then a presumption that the consensus of the market reflects, at any point, an estimate of future EPS which is the best possible from generally available data. Since the abnormal rate of return measures the extent to which the market has reacted to errors in its previous expectations, the abnormal rate of return can be used to assess the predictive accuracy of any device which attempts to forecast a number that is relevant to investors. To our knowledge, Ball and Brown (1968) were the first to make use of this fact.

Of particular importance is the presumption of a forecasted earnings number which is the best possible given the available data. Criteria 1 and 3 both provide information coincident with this presumption since statistically misspecified models or less accurate forecasts imply a departure from the market's expectation model.

The rationale associated with Criterion 2 was outlined by Foster [1977] and is stated as follows:

This analysis examines whether there is an association between unexpected earnings changes and relative risk

adjusted security returns. Given a maintained hypothesis of an efficient market, the strength of the association is dependent on how accurately each expectation model captures the market's expectation...

## 2.20 Population Studied

Data pertaining to the population of 267 calendar year firms was obtained from the Compustat quarterly and CRSP monthly tapes. For a firm to be included in the population it was required to have no missing EPS data for the 64 consecutive quarters beginning with the first quarter of 1962 and no missing returns data for the years 1970 through 1978. This provided a sample period from 1962 through 1977. The EPS number used was primary earnings per share excluding extraordinary items and discontinued operations, adjusted for capital changes. The return figure selected from CRSP included both dividend and price change components.

Note that, unlike previous research, all firms which met the survivorship test were retained for analysis. We define this group to be the population of interest and make no attempt to generalize to a larger number of years or group of firms. To use statistical testing to make inferences about a larger group of firms would be unwarranted because there is no reason to believe that firms which fail to meet the survivorship test are the same as those that do. In fact, a priori reasoning indicates that firms meeting the test are very likely to be larger and older than the average. Also attempting to generalize across all years would be unwarranted because structural changes in the economy might produce a shifting in the relative performance of different forecast methods. Even if this were not a problem, in order to generalize to all years, it would be necessary to obtain a reasonably large random sample of years. This is not possible because of limited data availability.

Since statistical testing is used for making inferences about a larger population and under the circumstances we felt that such inferences would be unwarranted, no statistical tests are presented in this paper. Instead, our goal is to present results for an entire population which is of interest in its own right.

#### 2.40 Model Estimation

All of the foregoing models were estimated for all of the population firms. The years of 1974 through 1977 were used as hold-out periods and were used in studying forecast accuracy and capital market performance. Therefore, the 267 firms were each modeled 16 times, once for each method using pre-1974 data (48 quarters in the base period) and again for each method (49 quarters in the base period) using all data prior to the second quarter of 1974, etc. (The BJ models were re-identified each quarter.) The result was that each model made predictions for four quarters into the future for each of the 16 base periods in the hold-out period. The use of the forecasts is discussed in a later section of this paper.

### 3.0 Summary of Diagnostic Statistics and Introduction of the Transfer Function Model

#### 3.10 Summary of Diagnostic Statistics

Table 1 presents a summary of diagnostic statistics for all of the above models. The purpose of this table is to provide evidence with respect to how well the models are specified. Therefore table 1 presents both residual autocorrelation and residual crosscorrelation (with the market earnings index<sup>1</sup>) statistics. The former are important

because if the residual error at time  $t$  is correlated with the residual error at a previous time, then it is possible to use this relationship to predict the error at time  $t$  and therefore improve the model. The same line of reasoning applies for the crosscorrelation between the residual and the market earnings index.

Table 1 also gives the average squared correlation ( $R^2$ ) coefficients. These have had the usual interpretation as being the percentage of variation in the dependent variable accounted for by the model.<sup>2</sup>

[Table 1 about here]

The auto/crosscorrelation statistics represent the percentage of times (expressed as a decimal) that a given coefficient was significant given an alpha error of .05 for each test. For example, for the BB model the lag one autocorrelations were significant 5.17% of the time. Also, for this model, the crosscorrelations between the market earnings index at time  $t-1$  and the model residual at time  $t$  were significant 14.91% of the time.

Inspection of the data indicates very serious specification problems for the BK and F models. For example, both models have significant fourth order (lag 4) residual autocorrelations over 50% of the time. These percentages are excessively high since, due to an alpha error of .05, we would expect approximately only a 5% rejection rate by chance. In addition, the BK model has severe crosscorrelation problems at an assortment of lags while the F model has crosscorrelation problems at the first few lags. As mentioned above these significant autocorrelations and crosscorrelations indicate that the model errors (residuals) are predictable and therefore the models are improvable.

A second indication of the data is that all of the univariate models suffer from excessive crosscorrelation at the first few lags. For example, the BR model has a 25.51% significance rate at lag 0 and approximately a 12% significance rate at the next 3 lags. These results indicate that the market earnings index can be used to predict the error of the univariate models. This implies that a multivariate time series model incorporating both the index and individual earnings series would be useful.

It should be noted that the BB model is based on annual data and its correlation significance tests were based on only 11-14 data points (annual changes). This is important since the standard error of correlation is roughly proportional to  $\frac{1}{\sqrt{N-K}}$  where N is the number of data points and K is the lag. The result is that at lag 1 the autocorrelation must exceed .59 in absolute value (when the sample size is 12) for the test to reject. Therefore, the BB individual tests have a lower power than other tests resulting in rejection percentages which are conservative.

In summary, the BK and F models appear to be very poorly specified while all of the univariate models appear to suffer from excessive crosscorrelation with the index. This implies that these models can be improved upon by generalizing them to transfer function models. This is described below.

### 3.20 Transfer-Function Model

Because of the diagnostic inadequacies in the above models, we identified a premier transfer function model.<sup>3</sup> By a premier model we mean one which is not individually identified for each firm but rather a single model is used for all firms. Previous research with univariate

time-series models has found this approach more fruitful because of the problem of search bias (i.e., excessive random variation leads to the selection of a wrong model when identified on a firm by firm basis). In addition, Hopwood [1980] found the transfer function identification process suffers from the same problem, but to a higher degree.

Therefore, a transfer-function model was identified based on the frequency of significant average autocorrelations and crosscorrelations. The result was a model of the form:

$$(1) \quad y_t - y_{t-4} = \theta_0 + w_0(x_t - x_{t-4}) + \phi_1 n_{t-1} + \theta_4 a_{t-4} + a_t$$

where  $y_t$  represents earnings,  $x_t$  the market earnings index,  $n_t$  the noise series (computed as  $n_t = y_t - y_{t-4} - \hat{\theta}_0 - \hat{w}_0(x_t - x_{t-4})$ ) and  $a_t$  the uncorrelated white noise residual series. Also  $\{\theta_0, w_0, \phi_1, \theta_4\}$  are the model parameters which must be statistically estimated.

While (1) is generically referred to as a transfer function, it is technically correct that  $\theta_0 + w_0(x_t - x_{t-4})$  is the transfer function while  $\phi_1 n_{t-1} + \theta_4 a_{t-4} + a_t$  is the noise model. Note that the result is that the transfer portion of the model is a bivariate regression model on seasonal differences while the noise model is the BR model. Using the language of Hopwood [1980],  $\theta_0$  is a (Type 8) deterministic trend constant,  $w_0$  is a (Type 9) input lag parameter,  $\phi_1$  is an (type 1) ordinary first order autoregressive noise model parameter and  $\theta_4$  is a (Type 6) seasonal fourth order seasonal moving average parameter. This model will henceforth be referred to as AM1 (author model 1). Also, a second model was theoretically derived based upon assumptions with respect to the earnings and index series. This model is derived in appendix 1 and will henceforth

be referred to as AM2. This model is virtually identical to AM1 but contains one additional term  $\theta_4 w_0 [(x_t - x_{t-4}) - (x_{t-1} - x_{t-5})]$  which is a seasonal input lag with a parameter constrained to be the product of  $\theta_4$  and  $w_0$ . A priori we would expect this parameter to be small since its product components are likely to be considerably less than one in absolute value. The result is that the estimation procedure is unlikely to satisfactorily resolve this parameter from noise without a very large population (e.g., several hundred data points). Nevertheless, we include it in the remainder of this study for completeness.

Table 2 gives the diagnostic statistics for both AM1 and AM2. Note that for both autocorrelations and crosscorrelations the models are fairly well specified. The crosscorrelations at lags 2 and 3 are slightly large, but investigation found that these could be traced to a severe one quarter slump of General Motors Corporation which affected the index.

[Table 2 about here]

#### 4.0 Application of the Models to the Capital Market

##### 4.10 Design

The market model of the form:

$$(2) \quad E[\ln(1 + R_{it} - R_{ft})] = B_j \ln(1 + R_{mt} - R_{ft})$$

was estimated, where (2) is the log form of the Sharp-Lintner [Lintner, 1965] capital asset pricing model and  $R_{it}$  represents the return on asset  $i$  in period  $t$ ,  $R_{mt}$  represents the return in period  $t$  and  $R_{ft}$  is the risk free rate of return in period  $t$ . The estimation was done using ordinary least squares regression and was done for each year in the hold-out period. The estima-

tions were done in each case by including monthly data for the 5 years preceding the hold-out year.<sup>4</sup> The residuals from these models when applied to the hold-out years (the twelve months up to and including the annual earnings announcement date), constitute risk-adjusted abnormal returns. The market index used was the value weighted market index containing dividend-price returns as supplied on the CRSP tape.

The next phase was to estimate the association between the unexpected annual earnings from the EEM's and the annual cumulative abnormal returns (CAR). (These were computed by adding the monthly returns.) This approach was outlined by Foster [1977] and is again stated as follows:

This analysis examines whether there is an association between unexpected earnings changes and relative risk adjusted security returns. Given a maintained hypothesis of an efficient market, the strength of the association is dependent on how accurately each expectation model captures the market's expectation.....

Foster applied this approach assuming a long investment given that the unexpected earnings was positive and a short investment given that it was negative. He then proceeded to measure the abnormal returns for different forecast methods given this strategy.

Since Foster's research, there has been an increasing knowledge of the fact that, for purposes of measuring association, this approach can be improved upon. For example, Beaver Clarke and Wright [1979] showed that the magnitude of the unexpected earnings is an important determinant of the size of the associated abnormal return (also see Joy et al. [1977]). Furthermore, Ohlson [1979, p. 526] analytically demonstrated that under certain conditions, the private value of information "for a decentralized strategy was simply the average  $R^2$  (per unit of time) between signals and residuals."

We therefore measured association via Spearman's rank correlation between the scaled  $((\text{Actual} - \text{Predicted})/\text{Predicted})$  unexpected earnings of the individual models and the residuals (annual CAR) and averaged these results across the 4 hold-out years. We used rank correlation because the scaled unexpected earnings were not normally distributed.

#### 4.20 Empirical Results

Table 3 presents the squared rank correlation data. Note that several models, previously not discussed, have been added. These are BKF, AM1F, AM2F and BBF. The postscript of "F" denotes that forecasts are ex ante which were based on predicted values of the market earnings index.<sup>5</sup> For the multivariate models without the postscript, the actual value of the index was used to form the ex post forecasts. Also by their very structure the univariate models are all ex ante.

[Table 3 about here]

The results indicate that the ex post multivariate models (except the BK model which was shown to be severely misspecified) have a higher association than the univariate models. The BB has the highest  $R^2$  statistic of .12165. The performance of the BB model is surprising since it uses the same data as the other multivariate models, but uses it in an annualized form. One might expect the aggregation from quarterly to annual form to produce loss of information. Also the BB model is estimated on only one fourth the amount of data as the quarterly univariate and bivariate models and this resulted in a very small number of data points (i.e., 11 to 14) for estimation. For example in the 12 year case there were only 9 degrees of freedom since there are 2 parameters estimated and an additional degree of freedom is lost

because of differencing. Finally, as previously mentioned, the BB model does not specifically consider the time series properties of the individual firm earnings.

In summary the data does not support the use of a univariate model as discussed by Foster [1977], to approximate the market expectation for earnings. In addition the data does not support the use of the BK model.

#### 4.30 Ex Ante Versus Ex Post Forecasts: Further Explanation

Further examination of Table 3 reveals that in general the ex post models have higher associations than the ex ante models do. This is undoubtedly much of the reason that the BB model outperforms the univariate models. This is because univariate models are not capable of incorporating the ex post information of the most recent value of the market index. At first glance this might appear to be an obvious conclusion, and it would be except for the fact that the univariate models have the advantage over the BB model in that they specifically incorporate the time series properties of the individual firm earnings.

This leads us to an empirically verifiable question. Do the time series models capture information that could be used to improve the association for the BB model? To answer this question, we computed the partial rank correlation between the non-BB models' unexpected earnings and the abnormal return while holding the BB unexpected earnings constant. The meaning of such a partial correlation is that any model which has a non zero coefficient captures information that could be used to improve the BB market association. Stated differently such a model would contain information independent of that captured by the BB model.

The results of this procedure are presented in table 4. Note that in all cases the partial correlations are small and less than 2.5%. There appears, however, to be a discernible pattern. First, note that the ex ante multivariate models have substantially smaller partial correlations than other models. Among the remaining models the BK and F models are the lowest at about 1.3% and 1.5% respectively. Recall that both of these models did very poorly on the diagnostic statistics. Finally, all other models are remarkably close with statistics near 2%. This implies that the univariate time series models are systematically capturing information not incorporated into the BB model. This also implies that it might be possible to combine the BB with one of these models to form a model which incorporates both annual and quarterly data. Such a model would be complex and is the subject of further investigation by the authors.

[Table 4 about here]

## 5.0 Empirical Accuracy Results

The ability to predict annual forecasts from quarterly earnings was studied. Table 5 presents the accuracy results for these forecasts. Panel 1 gives the mean absolute percentage forecast errors where errors larger than 1 were truncated to 1.<sup>6</sup> The four columns represent the accuracy as the end of the year approaches. For example, the average error for GW made 4 quarters prior to the end of the year is .2683588; the average error for the GW made three quarters prior to the end of the year is .2173826. In all cases, realizations are substituted for forecasts as the year end approaches. Therefore, for example, the GW annual forecast 3 quarters prior to the end of the year is based

upon the realized value of the first quarter's forecast plus the forecasts (made from the end of the first quarter) for the second, third, and fourth quarters.

[Table 5 about here]

Note that the results of panel 1 are fairly consistent with those of the capital market, and the multivariate ex post models (with the exception of the BK model) provide the most accurate forecasts.<sup>7</sup> Again, the BB model places first and AMI second. Panel 2 presents the same data, but for each forecast the 13 models are ranked (from 1 to 13) and the mean ranks are substituted for the mean absolute percentage errors. This ranking approach has the advantage of not depending on a particular error metric and also avoids the need to standardize by using a percentage error metric (and therefore, eliminates the need to truncate because of small denominators). Note that the results are fairly consistent with those presented above but in this case AMI places first and BB and GW are approximately tied for second place<sup>8</sup> (four quarters prior to year end).

#### 5.10 Ex Ante Versus Ex Post Accuracy

The multivariate ex ante forecast error can be broken down as follows:

$$\text{Ex ante Error} = \left( \text{Actual income} - \text{Ex post forecast} \right) + \left( \text{Ex post forecast} - \text{Ex ante forecast} \right)$$

Note that this error is the ex post error plus a second term which is attributable strictly to error in forecasting the market index. Recall, from above, that the ex post error yields a stronger market association than the ex ante error. This implies that the market does not react to

the second term. This seems reasonable since this term is an error effect which is common to all firms (i.e., due to the level of the market) and does not provide the market with information unique to specific firms. The conclusion then is that the ex post error is the relevant number for purposes of measuring how well a given model approximates the capital market's expectation.

We now turn our attention to the secondary purpose of this study which is to evaluate the models based on ex ante accuracy. One reason for the study of ex ante forecasts is they have value in themselves for purposes other than serving as EEM's. For example, Norby [1973] found that 99% of responding financial analysts stated that they use ex ante forecasts in their decision making process. (In addition Collins and Hopwood [1980] present a discussion of the importance of these numbers to the Financial Accounting Standards Board and the Security Exchange Commission.) It is in this light we discuss the secondary purpose of this paper, ex ante forecast accuracy.

The data in panel 1 of Table 5 (mean absolute percentage errors) indicate that among the multivariate ex ante models the BBF and BKF consistently perform worse than the models which incorporate time series properties. On the other hand, AM1F (and AM2F) shows an overall marked tendency to produce the most accurate ex ante forecasts. Note that AM1F outperforms all three of the premier models in all cases except one (two quarters prior to year end) where the BR provides the most accurate forecast. Nevertheless, even in this case AM1F provides the second most accurate forecast. Also note that the BJ method generally has errors which are large among those of the other models. However in the last quarter of the year the BJ has the smallest mean

error. This is probably period specific since previous research [Collins and Hopwood, 1980] has shown that while the performance of the BJ method varies, it does not consistently produce more accurate forecasts.

Panel 2 of table 5 presents the mean ranks. Note that when evaluated from the standpoint of ex ante forecasting these data are not consistent with previous results of this paper. For example, at 4 and 3 quarters prior to year end the F model does better than the BR model. (Recall that the F model has a severe seasonal misspecification.) These results can be explained by the fact that while ranks are not subject to outlier problems they do ignore the magnitude of the data. Because of these problems and because previous research has shown that the market is sensitive to the magnitude of errors [Beaver, Clarke and Wright, 1979] we feel that these ranks are of limited usefulness here. Nevertheless we include them for completeness.

## 6.0 Summary and Conclusions

This study primarily investigated univariate and multivariate statistical models in the context of their relative ability to serve as a market earnings expectation model (EEM). As a secondary consideration we evaluated relative ability of these models to generate ex ante forecasts. Included were univariate time series models, bivariate regression models and two bivariate multiple time series (transfer function) models developed by the authors. To accomplish the primary purpose, the models were compared on: (1) how well they are specified based upon diagnostic statistics; (2) their ability to perform in a capital market context; and (3) ex post forecast accuracy.

The results indicated that neither the univariate time series models nor the regression model of Brown and Kennelly provided an adequate model for the market expectation of earnings. It was found that the model used by Ball and Brown provided the simplest and most adequate market expectation. It was also found among models using quarterly data that a simple transfer function (author model 1) provided the best model. Such a model clearly out performed all other quarterly models based on all of the criteria used to evaluate the relative ability of these models to approximate the market expectation of earnings.

Finally, the partial correlation statistics of market association indicated that the Ball and Brown model could be improved based upon information captured in the quarterly time series models. However, to realize such an improvement might require combining quarterly and annual data within one model. The resulting model would be complex and is the subject of future investigation by the authors.

The models were also evaluated based upon ex ante forecast accuracy. The data indicated that in this context the Ball and Brown model is very inadequate. Also, among the ex ante models the transfer function model provided the smallest mean absolute percentage forecast errors in three out of four quarters prior to year end. These results indicate future research on the time series properties of earnings should consider the more general transfer function model studied in this paper.

NOTES

<sup>1</sup>The market earnings index was computed as a weighted average of the individual firm EPS (excluding the firm being modeled).

<sup>2</sup>Care should be exercised in interpreting the  $R^2$  values. This is because they represent the percentage of variation explained on the series as modeled. Recall that different models do not all use the same type of differencing. The univariate models use a seasonal difference while the BK and BB use a consecutive difference. Also the BB uses annual data where the other models use quarterly data. Also a higher  $R^2$  for the BJ models may be due to "search-bias" (see Foster [1978, p. 104]) which means that while the BJ identification process produces better fitting models (due to the way it works), it may often choose inappropriate models because of random variation in the data. Aside from this problem the  $R^2$  results of the BR, F and GW are consistent with the accuracy results of Collins and Hopwood [1980].

<sup>3</sup>For a detailed discussion of transfer function modeling see Box and Jenkins [1970] and Hopwood [1980].

<sup>4</sup>For 1974 there were only 4 years of data available for regression estimation.

<sup>5</sup>The index predictions were based on applying the F model to the index. This model was identified based on the 267 different index series.

<sup>6</sup>Truncation was done because the error metric  $|(Actual - Predicted)/Actual|$  allows for a zero or near zero denominator and therefore an undefined or explosive number can occur.

Our analysis of the data revealed that truncation numbers larger than one gave unstable mean error rankings for the univariate versus multivariate models. Therefore to minimize the effect of outliers on the results we choose a value of one. Foster [1977] also used a value of one. Also the relative performance with a value of one is consistent with that based on a mean rank criterion which does not depend on the choice of an error metric. It is also consistent with the diagnostic and capital market results. Finally the percentage of truncation for models was about the same and averaged about 5% of the forecasts. The BBF model, however, had an incidence about 3 times as high as other models.

<sup>7</sup>Note that the relative performance of the univariate models indicates that there is no advantage to be gained by performing the costly process of identification. This is indicated by that fact that the BJ does not do better than the other models. Also the F model has a larger error than the other univariate models in three of the four quarters. Finally the BR and GW models are very close. These results are consistent with those of Collins and Hopwood [1980].

<sup>8</sup>Note that the relative performance of the univariate models here is somewhat consistent with that based on the mean absolute percentage error (MAPE) metric. Again there is no justification for the costly process of individual model identification. These results differ in that the GW model consistently performs the best whereas on the MAPE metric the BR model did better than the GW model for 2 of the 4 quarters.

<sup>9</sup>On our sample data  $\phi'$  averaged .77 and  $\phi$  averaged .67. Our analysis of diagnostic statistics indicated that the resulting model fits very well.

## APPENDIX 1

### Derivation of Author Model 2

It is possible to derive a single input transfer function model for two series given that the ARIMA models are known for both series. This appendix derives such a model based on the assumption that the EPS series follows the BR process and that EPS index follows a first order autoregression process with a seasonal difference. The literature has shown that the first assumption holds well [Collins and Hopwood, 1980] and the second assumption was made based upon identifying the index model from the sample data.

Assume that the index series ( $x_t$ ) follows a first order autoregressive model of the form ( $x_t$  and  $y_t$  will henceforth be assumed to be seasonally differenced)

$$(A1.1) \quad a_t = (1 - \phi B)x_t$$

and the earnings series ( $y_t$ ) follows the BR model

$$(A1.2) \quad (1 - \phi' B)y_t = (1 - \theta B^4)a_t'$$

Next add to the right hand side of (A1.1) a white noise series  $l_t$  which is assumed to be independent of  $x_t$ . The result is

$$(A1.3) \quad a_t = (1 - \phi B)x_t + l_t$$

Also (A1.2) can be solved for  $a_t'$  resulting in

$$(A1.4) \quad a_t' = \frac{(1 - \phi')B}{(1 - \theta)B^4} y_t$$

Next substitute the right hand side of (A1.4) for  $a_t$  in (A1.3) giving

$$(A1.5) \quad \frac{(1 - \phi'B)}{(1 - \theta B^4)} y_t = \alpha + (1 - \phi B) w_0 x_t + \epsilon_t$$

where  $\alpha$  and  $w_1$  have been added to correct for the fact that  $a'_t$  in (A1.4) and  $a_t$  in (A1.3) might be of different scale and correlated. Next multiplying both sides of A1.5 thru by  $\frac{(1 - \theta B^4)}{(1 - \phi'B)}$  we obtain

$$(A1.6) \quad y_t = \alpha' + \frac{(1 - \theta B^4)}{(1 - \phi'B)} (1 - \phi B) w_0 x_t + \frac{(1 - \theta B^4)}{(1 - \phi'B)} \epsilon_t$$

and assuming  $(1 - \phi'B)$  cancels with  $(1 - \phi B)$  (empirically we found these factors to be approximately equal<sup>9</sup>) we obtain the final model

$$(A1.7) \quad y_t = \alpha' + (1 - \theta B^4) w_0 x_t + \frac{(1 - \theta B^4)}{(1 - \phi'B)} \epsilon_t$$

which can be written in more conventional form

$$(A1.8) \quad y_t = \alpha' + w_0 x_t + \theta w_0 x_{t-4} + \phi' B n_{t-1} + \theta a_{t-4} + \epsilon_t$$

where  $n_t$  is the noise series.

The result is identical to AM1 but the term  $\theta w_0 x_{t-4}$  is added to the model.
